1.0 Circulatory system

- It is the movement of body fluids inside the body of animals so as to transport materials from the region of the formation to the region of utilization or disposal. A circulatory system is a
complex of structures involved in the flow of body fluids of an organism so as to accomplish transport of materials

• Circulation of body fluids can be of the following types

1. Intracellular circulation
   It occurs inside the individual cells through Cyclosis or cytoplasmic streaming. Examples: Paramecium, Amoeba.

2. Extracellular circulation
   In multi-cellular animals, the living cells are bathed in an intercellular or extracellular fluid which circulates in the body for transport of materials extracellular circulation can be
   a) Extra-organismic circulation: Outside water circulates in the body of an organism
   b) Intra-organismic circulation: It involves circulation of body fluid
   i) Parenchymal circulation
      In flatworms, fluid-filled spaces present in parenchyma tissue between the body wall and internal organs are used in the distribution of substances.
   ii) Coelomic Circulation
      Coelomic fluid is employed in the transport of substances, Pseudocelom is used for this purpose in roundworms. Hemocoel does so in arthropods
   iii) Blood vascular system
      It contains blood and a pumping structure (heart) for circulation of materials inside the body. Lymphatic system accompanies blood vascular system.

1.01 Functions of circulatory system
Open circulatory system

- Open circulation occurs in arthropods and mollusks.
- The blood is not completely enclosed within vessels, the heart pumps blood through arteries into large cavities or sinuses, where it mixes with interstitial fluid and bathes the cells of the body.
Blood is a combination of blood and interstitial fluid called haemolymph, while the spaces and lacrimal are together called haemocoel.

- The blood is slowly returned to the heart through small pores called Ostia e.g. arthropods (cockroach)

- Circulation is slower in an open system because, with some of the blood pooled in sinuses, the heart cannot build up enough pressure to make blood flow rapidly.

- An open system cannot achieve the high rates of oxygen transport that active animals require.

- Animals with open systems are either small and sluggish or use the open system only for the transport of food and wastes and use a different system for the transport of gases.

  - Respiratory pigment, if present, is dissolved in the plasma, no red corpuscles are present.

3.0 **Closed circulatory system**

- The closed circulatory system is a type of blood vascular system in which blood remains confined and flows inside blood vessels only, never coming in direct contact with body cells. It occurs in most annelids, cephalopod, and vertebrates. Annelids are the simplest animals to have closed circulatory system.

  - Flow of blood is
In prawn, the heart is arterial as it pumps only oxygenated blood. Vertebrate heart shows evolutionary development.

- Sinus venosus is a distinct sac which is specialized to receive venous blood. It opens into auricle.
- Conus/ truncus arteriosus is another similar sac into which ventricle opens for distribution of arteries.
- In fishes, the heart is two-chambered with an auricle/atrium and a ventricle. Both sinus venosus and conus arteriosus are present. There is a single circulation and heart pumps only venous (deoxygenated) blood to gill from where it passes to different body parts. Heart of fishes is therefore venous or branchial arteriovenous heart occurs in lungs fishes amphibians, reptiles, birds, and mammals because it receives both venous (deoxygenated and arterial (oxygenated) blood. there is double circulation, pulmonary (to and fro lungs) and systematic (to and fro other body parts).

- In amphibians, there are two auricles/atria.
- In amphibians, there are two auricles/atria, one ventricle, a sinus venosus and cons/ truncus arteriosus. Mixing of oxygenated and deoxygenated blood occur in the ventricle.
- In reptiles, the heart has two atria and an incompletely divided ventricle. Sinus venous is present but conus arteriosus has merged with ventricle and aorta.
- In crocodiles, the ventricle is almost completely divided through mixing of blood does occur.
- The heart is completely four-chambered in mammals and birds with neither sinus venosus nor conus arteriosus. There are two atria and two ventricles. There are two atria and two ventricles. The left part of the heart is connected with oxygenated blood.
(scarlet red) and right part with deoxygenated blood (purple red)

3.02 Artery

It is a blood vessel that carries blood away from the heart towards an organ. Artery generally contains oxygenated blood (deoxygenated in the pulmonary artery). The blood flows in an artery under alternate increased pressure and with jerks. Arteries are deep-seated with thick elastic wall and comparatively, narrows lumen. They become empty after death. Valves are absent. The wall is made up of three regions tunica external, tunica media or tunica adventitia is an outer coat made of loose connective tissue with abundant white (collagen) and fewer yellow (elastin) fibers as well as longitudinal smooth or unstriped muscle fibers. There is a well-developed external elastic lamina on the inner side. The middle coat or tunica media is thick having unstriped circular muscles and elastic connective tissue. The inner coat, tunica interna or tunica intima is also made of connective tissue. It has a number of folds. The lumen is lined by an endothelium of elongated flat thin
artery, tunica external, tunica media and tunica interna. Tunica Externa is the outer coat with loose connective tissue, abundant white, and fewer yellow fibers. It is well developed but external elastic lamina is not much differentiated. Tunica media is comparatively thinner in vein with a few smooth circular muscles. Tunica interna is similar to the artery but with fewer folds, less developed internal elastic membrane and less elongated endothelial tissues. Semilunar valves are made of folds of endothelium with some enclosed connective tissue.

3.04 Capillary

It is a very fine blood vessel where the wall is made of a single layer of the endothelium of tessellated cells. A fine intercellular cleft occurs between the adjacent endothelial cells. Basement membrane lies on the outside. Blood capillaries are formed by arterioles. They join to produce venule. The lumen of blood capillary is so fine that red blood corpuscles can pass through it in a single file. The WBC can come out of them through the process of diapedesis. Because of their extremely thin walls, blood capillaries take part in the exchange of materials between blood and tissue fluid. In lungs, they pick up oxygen and give out CO₂ through diffusion. All the blood capillaries are not functional all the time. Some of them work only at the time of intense activity. Their working is controlled by precapillary sphincters present in the area of their origin.

3.05 Arteriovenous anastomosis
It is a direct vascular connection between an arteriole and venule bypassing capillary supply. The connection occurs in certain exposed parts like fingertips, nose, pinnae, eyelids, lips, tongue etc. It is meant for controlling blood supply and temperature of the exposed parts.

3.06 Vascular plexus

Anastomosis of blood vessels is like arteries in certain regions to provide extra blood e.g. cutaneous plexus, papillary plexus, and nasal plexus.

5.0 Blood

It is complex mobile fluid connective tissue of reddish colour in which the fluid matrix is not synthesized by the contained cells. An adult human has 5-5.5 liters of blood. pH is 7.4. Blood consists of two parts, plasma and blood corpuscles (formed elements).

5.01 Plasma

- It is a slightly alkaline non-living intercellular substance which constitutes about 60% part of the blood. It is a pale yellow but transparent and clear fluid.
iii) Maintenance of blood pH
iv) Body immunity
v) Prevention of blood loss
vi) Conducting heat to skin for dissipation
vii) Uniform distribution of heat all over body

5.01.02 Blood glucose

- Usually blood glucose level is about 80-100 mg per 100 ml of blood 12 hours after a normal meal
- It blood glucose level exceeds 180 mg per 100 ml, it starts appearing in the urine. This condition is called glycosuria. If it
- Hemoglobin is a conjugate protein which is made up of a protein called globin and a non-protein group heme (=haeme) hence the hemoglobin.
- Hemoglobin is oxygen-carrying pigment. 100ml of blood of a normal man contains 15g of hemoglobin and of normal woman an average of 13g of hemoglobin
- Erythropoiesis is the process by which red blood cells are produced. In human adults, this usually occurs within the bone marrow.
monomorphic nucleus).

→ The life of granulocyte is normally 40 to 8 hours circulating in the blood and another 4-5 days in the tissue

→ Monocytes have a short lifespan of 10-20 hours. The lymphocytes have life span of few days or months or years

→ Granulocytes are of three types (neutrophils, basophils, eosinophils) while agranulocyte are of two types (Monocytes and lymphocytes)
Lymphocytes: Large nucleus with granule-free pale blue cytoplasm, 30% of total leucocytes, manufactures globins some of which function as antibodies in immunological reactions. Lymphocytes have a size of 7-10 μm in diameter and 1-2 μm thick. Red colour is due to them, nucleus stains more deeply with basic dyes than surrounding cytoplasm. Large lymphocytes have 10-14 μm in diameter and 1-2 μm thick. Red colour is due to them and more cytoplasm. On basis of site of maturation, two kinds: β-lymphocytes, and T-lymphocytes.

Monocytes: Largest leucocytes, 10-18 μm kidney-shaped nucleus, 5-6% of total leucocytes motile, Phagocytic, scavengers, production of interleukin and pyrogen.

5.02.04 Thrombocytes (blood platelets)

There are about 250,000 platelets in cubic millimeters of blood. Increase and decrease in the number of platelets is known as thrombocytosis and thrombocytopenia respectively.
Blood coagulation (blood clotting)

When an injury is caused to a blood vessel, bleeding starts which are topped by a process called blood clotting or blood coagulation.

First step: At the site of an injury, the blood platelets disintegrate and release a phospholipid called platelet factor-3 (Thromboplastin). Injured tissues also release a lipoprotein factor called thromboplastin. These two factors combine with calcium ions $\text{Ca}^{+2}$ and certain protein of the blood to form an enzyme called prothrombinase.

Second step: The prothrombinase inactivates heparin in the presence of calcium. Prothrombinase catalyzes the breakdown of Prothrombin into an active protein called thrombin and some small, peptide fragments.

Third step: Thrombin acts as an enzyme and first brings about depolymerization of these monomers. Later thrombin stimulates polymerization of these monomers into long insoluble fibers – like polymers called fibrin. The thin, long and solid fibers of fibrin from a dense network upon the wound and trap blood corpuscles to form a clot. The clot seals the wound and stops bleeding. Soon after the clot starts contracting and a pale yellow fluid, the serum, starts oozing out. This serum is blood plasma minus fibrinogen and blood corpuscles.

Vitamin K is essential for blood clotting as it is necessary for the synthesis of Prothrombin in the liver.

**Intrinsic Pathway**

- Collagen
- Factor 8 and calcium
- Factor 5 and calcium
- Thrombin further activates factors 5, 7, 8, 11, 13
- Prothrombin
- Platelets
- Thrombin
- Fibrinogen
- Fibrin
- Stabilised cross-linked fibrin
- Factor 13

**Extrinsic Pathway**

- Calcium
- Factor 5 and calcium

THE COMMON PATHWAY BEGINS FROM FACTOR X

Red arrows indicate which clotting factors need to be present in order to activate the next part of the clotting process.
Factor III

Name: Thromboplastin / Tissue Factor
Source: Platelets (intrinsic) and damaged endothelium (cells) lining the blood vessel (extrinsic).
Pathway: Both extrinsic and intrinsic
Activator: Injury to blood vessel
Action: Activates factor VII (VIIa).

Factor IV

Name: Calcium
Source: Bone and absorption from food in gastrointestinal tract
Factor VII
Name: Proconvertin / Serum prothrombin conversion accelerator (SPCA) / stable factor
Source: Liver
Pathway: Extrinsic
Activator: Factor III (tissue factor)
Actions: Activates Factor X which works with other factors to convert prothrombin into thrombin.

Factor VIII
Name: Anti-hemolytic factor / antihemophilic factor (AHF) or globulin (AHG) / antihemophilic factor A
Source: Endothelium lining blood vessel and platelets (plug)
Pathway: Intrinsic
Activator: Thrombin
Actions: Works with Factor IX and calcium to activate Factor X.
Deficiency: Hemophilia A
Factor IX
Name: Christmas factor / Plasma thromboplastin component (PTC) / Antihemophilic factor B
into thrombin. This reaction is made faster by activated Factor V.

Factor XI
Name: Plasma thromboplastin antecedent (PTA) / antihemophilic factor C
Source: Liver
Pathway: Intrinsic
Activator: Factor XII + prekallikrein and kininogen
Actions: Works with calcium to activate Factor IX.
Deficiency: Hemophilia C

Factor XII
Name: Hageman factor
Source: Liver
Pathway: Intrinsic
Activator: Contact with collagen in the torn wall of blood vessels
Actions: Works with prekallikrein and kininogen to activate Factor XI. Also, activates plasmin which degrades clots.

Factor XIII
Name: Fibrin-stabilizing factor
Source: Liver
Activator: Thrombin and calcium
Actions: Stabilizes the fibrin mesh network of a blood clot by helping fibrin strands to link to each other. Therefore it also helps to prevent fibrin breakdown (fibrinolysis).

Prekallikrein
Source: Liver
Pathway: Intrinsic
Actions: Works with kininogen and Factor XII to activate Factor XI.
Kininogen
Source: Liver
Pathway: Intrinsic
Actions: Works with prekallikrein and Factor XII to activate Factor XI.

7.0 **Functions of blood**

i) Transport of food materials: Blood transports the digested food from the alimentary canal to the different body cells

ii) Transport of respiratory gases: Oxygen is carried from the respiratory organs to the tissues and carbon dioxide from the tissue to the respiratory organ by blood.

iii) Transport of hormones: Hormones are carried by blood from the endocrine glands to the places of use

iv) Transport of excretory matter: Blood transport the excretory matter to the kidney or other excretory organs.

v) Transport of heat: Blood allows the transfer of heat from the deeper tissue to the surface of the body where it can be lost.
xii) Maintenance of physiological co-operation: Blood maintains a physiological co-operation between parts of the body by circulating from one to other parts.

8.0 **Blood group**

- Karl Landsteiner reported first time ABO blood groups in a human being (1900). AB blood group was found out by de Castellan and Steini (1902)
- If a blood transfusion is made between an incompatible donor and recipient, the reaction of antigen on the cells and antibodies in the plasma produce clots that clog capillaries.

8.01 Rh (rhesus) blood group

- A protein named Rhesus antigen is present on the surface of red blood corpuscles in many persons. It was discovered in 1940 by Landsteiner and Wiener in the blood of Rhesus monkey, hence its name.
Rh+ blood given to Rh- person produces an anti-Rh factor ‘a’. The first baby is safe due to late development of anti-Rh factor ‘a’.

However, the second Rh+ baby will either die in foetus stage or be born anemic with several abnormalities due to the disintegration of red blood cells (erythroblastosis foetalis) by anti-Rh factor ‘a’ (anti-Rh globulin is available to overcome the defect) and consequent production of excess bilirubin. The latter can damage the brain of the infant. However, the reverse does not have the effect.

Oswal Hope Robertson is the creator of the first blood bank.

8.02 Importance of blood groups

i) Knowledge of blood group is essential for blood transfusion

ii) Rh compatibility is required for both marriage and transfusion in order to prevent erythroblastosis

iii) Preliminary information about disputed parentage and progeny is provided by blood grouping.

iv) Blood grouping is used in the forensic identification of blood stains.

9.0 Human Heart

- It is a reddish conical muscular mesodermal hollow organ of an about 12cm length 9 cm breadth, weighs about 300gm and lies behind the sternum in the mediastinum space of holder cavity in between the two lungs. Broader base is upwards.

- The mammalian heart comprises of four complete chambers two ventricles and two auricles (atria)
• Heart wall consists of connective tissue, blood vessels, and cardiac muscle fibers. The latter form a cross-connected network for smooth passage of constriction wave. The cardiac muscle or myocardium does not tire due to
  a) Alternate rest and activity
  b) Non-formation of lactic acid
• The heart is covered by a double fibrinogenous sac or pericardium. It has two components outer non-distensible tough fibrous pericardium (prevents excessive expansion of heart) and inner thin serous pericardium.
• Serous pericardium has two thin secretory membranes,
  (i) outer parietal have two sub layers
  a) Outer: Fibrous connective tissue
     b) Inner: Simple squamous epithelium
  (ii) and inner visceral or epicardium made up of simple squamous epithelium
(v) Limits heart motion
(vi) Reduces friction between the heart and surrounding tissues
(vii) Protects the heart against infection

- There is a depression or coronary sulcus between atria and ventricles, interatrial sulcus (two parts, anterior and posterior) between two ventricles. Coronary arteries are housed in these sulci. They supply blood to walls of the heart.
- Atrial appendages are protruded part of atria which overhangs the ventricles. Low ridges occur internally in the region of the
• Opening of coronary sinus and Eustachian valve at the opening 
of inferior vena cava.

• Backflow in superior vena cava is prevented by the obliquity of 
opening. The left atrium/auricle receives oxygenated blood 
from two lungs through four pulmonary veins. Right and left 
ventricles are separated by an interventricular septum.

• The left ventricle is larger, includes the apex part and has an 
extra thick wall as compared to right ventricle due to its 
mechanical requirement of pumping oxygenated blood to all 
parts of the body, walls of ventricle possess a network of low 
ridges or columnae carneae and a few large muscular projection 
or papillary muscles/ musculuspapillaris).

• Right ventricle contains a moderator band that extends 
between upper papillary muscle and inter-ventricular septum. 
Atria opens into ventricles through atrioventricular apertures is 
guarded by valves. Right atrial- ventricular aperture is guarded 
by tricuspid valve possessing three flaps and left 
atrioventricular aperture is guarded by bicuspid and mitral 
valve possessing two flaps.

• The flaps of the valves are held in their position by fine 
inelastic cords or chordaetendineae connected to papillary 
muscles. Left ventricle opens into the aorta. The opening is 
guarded by an aortic semilunar valve between two.
10.0 Conduction of heart beat

- The automatic rhythmicity of the heart is its ability to contract spontaneously at a regular rate.
- In practice, this represents apex or ventricular beat with an advantage of 72/minutes in an adult human. It is high in infants and low in aged persons. Similar heart beat is fast in small animals (200/min in Rabbit and 500/min in Sparrow) and low in large animals (25 /min in elephant) as well as cold-blooded animals (64/min in frog).
the ventricles.

- This wave of contraction next reaches the atrioventricular (AV – node) or pacesetter is stimulated to emit an impulse of contraction spreading to the ventricular muscle in the atrioventricular bundle and the Purkinje fibers.
- The atrial muscle fibers are separated from those of the ventricles by a fibrous tissue ring. These are no functional continuity between the atria and ventricles. They only conducting tissue between the atria and the ventricles is the atrioventricular bundle or the Bundle of His).
- The atrioventricular bundle (Bundle of His) was discovered by His (1983) and consists of a set of specialized muscle strands originating from AV node and pass downwards into the inter-ventricular septum. This bundle then divided into the left and right bundle branches, one going to each ventricle.
• Within the myocardium of the ventricles, the branches break up into a network of fine branching, anastomosing filaments of fibers known as Purkinje fibers.
• The bundle of His and the Purkinje fibers convey the impulse of contraction from the AV node to the myocardium of Ventricles.

10.01 Pace-maker

• SA node is called natural pacemaker of heart as impulse generated by it spreads to both atria and through AV node to ventricles for their rhythmic contraction.
• Disruption or insufficiency of any component of this impulse conducting system results in slowing down or irregularity of heart rhythm or independent contraction of atria and ventricles. Failure of the atrial impulse to pass into ventricles for a few seconds to few hours is called ventricular escape or
vena cava-right atrium and allowed to rest against the tip of the right ventricle.

- A pacemaker is liable to be influenced by microwave ovens, metal detectors, electric shaver’s cell phone etc.

10.02 Cardiac cycle

- The cardiac cycle consists of one heart or one cycle of contraction and relaxation of the cardiac muscle. The contraction phase is called the systole while the relaxation phase is called diastole.
pulmonary trunk and aorta as the semilunar valves open.

**Beginning of ventricular diastole:** The ventricles relax and the semilunar valves are closed. This causes the second heart sound.

**Complete ventricular diastole:** The tricuspid and bicuspid valves are open when the pressure in the ventricles falls and blood flows from the atria into the ventricles. Contraction of the heart does not cause this blood flow. It is due to the fact that this blood flows. It is due to the fact that the pressure within the relaxed ventricles is less than that in atria and veins.
In single cardiac cycle of human

1. Atrial systole = 0.1 sec
2. Atrial diastole = 0.7 sec      total 0.8 sec
3. Ventricular systole = 0.3 sec
4. Ventricular diastole = 0.5 sec     total 0.8 sec
Joint diastole 0.8-0.4 = 0.4 sec  is a period during which entire heart is in diastole

Heart sounds
- There are sounds produced during heart beat due to closure of valves
- Lubb (S1) first sound, systolic sound is the first heart sound which is dull, loud or low pitched, of long duration (0.16 and 0.19 seconds) and is produced due to closure of atrioventricular valves (tricuspid and bicuspid valves)
• Dup (S₂, second sound, diastolic sound) is the second heart sound which is sharp high pitched, of shorter duration (0.1 sec) and is produced due to the closure of semilunar valves at the base of great arteries. A pause or gap occurs between the second sound and the first sound of next cycle. It coincides with ventricular diastole.

• Incomplete closure of valves due to disease or other defect produces abnormal heart sound called murmur. Heat sounds are listened by means of an instrument called stethoscope.

12.0 Cardiac output
The volume of blood pumped by each ventricle per minute is called the cardiac output.

It is determined by multiplying the heart rate by the volume of blood ejected by each ventricle during each beat, which is called the stroke volume.

\[
\text{Cardiac Output} = \text{Heart Rate} \times \text{stroke volume}
\]

\[
= 72 \text{ beats/min} \times 0.08 \text{ litre/beat} = 5.5 \text{ litres/min}
\]

Cardiac index is the minute volume per sq.m. of body surface area. Its normal value is 3.3 litre/min/sq.m

13.0 **Regulation of heart beat**

13.01 Neural regulation

The cardiac center lies in the medulla oblongata of the brain. The cardiac center is formed of cardio-inhibitor and cardio-accelerated parts. The former decreases the rate of heart beat and the latter accelerates it. The cardio-inhibitor is connected with the heart through vagus nerve (it carries – parasympathetic nerve fibers) and cardio accelerator through sympathetic nerve fibers. Sensory fibers extended from the receptors present in the superior vena cava aorta and carotid sinuses to the cardiovascular center in the medulla oblongata. The impulses received from the aorta and carotid sinuses decrease the heart rate, whereas the impulses from Vena Cava increase the heart rate.

13.02 Hormonal regulation

Adrenaline and noradrenaline hormones are secreted by the medulla of the adrenal glands. Noradrenaline accelerates the heart beat under normal conditions while adrenaline does this function at
These hormones directly influence the SA node. Thyroxine hormone secreted by thyroid glands increases oxidative metabolism of the body cells. This requires more oxygen and thus indirectly increases heartbeat.

Body temperature also affects the pacemaker. Just 1°C rise in temperature increases with exercise to provide additional oxygen and food to muscles.

14.0 Electrocardiogram (ECG)

- ECG is a graph record of the electrical current produced by the excitation of the cardiac muscles. The instrument used to record the changes in an electrocardiograph. Waller (1887) first recorded the electrocardiogram but Einthoven (1906) studied ECG in detail and got the Nobel Prize. He is also considered...
“father of the electrocardiography
The QRS wave (complex) begins after a fraction of a second of the P wave. It begins as a small downward deflection (Q) and continues as large upright (R) and triangular wave, ending as downward wave (S) at its base. It represents ventricular depolarization (ventricular contraction).

The T wave is a dome-shaped wave that indicates ventricular repolarization (ventricular relaxation).

Each large square represents 0.2 seconds. The normal P-R interval is 0.12 to 0.2 second. Normal QRS complex duration is 0.12 second. The normal Q-T interval is 0.4 second.

- Enlargement of the P wave indicates enlargement of atria. During atherosclerotic heart diseases and rheumatic fever, the P-R interval is lengthened. This is due to the inflammation of atria and AV node.
- The enlarged Q and R waves indicate a myocardial infarction (heart attack). The S-T segment is elevated in acute myocardial infection and depressed when the heart muscle receives insufficient oxygen.
- T wave is flat when the heart muscles receive insufficient oxygen as in atherosclerotic heart disease. It may be elevated when the body’s potassium level is increased.
- When ECG of person to be recorded, four leads (metal electrodes) are attached to the arms and legs. It is done after lining and putting special jelly, which improves electrical conduction. With the help of rubber suction cup, an additional electrode is placed on the chest. Now the electrocardiograph is switched on which detects and amplifies the electrical current of the heart and transmits to the recording pen. The latter draws a wavy line that is called deflection wave.
The importance of ECG is that it gives accurate information about the heart. Therefore, ECG is of great diagnostic value in cardiac diseases.

Blood pressure

It is the pressure exerted by the flow of blood on the walls of arteries and measured as millimeters of mercury by the instrument is called sphygmomanometer (Riva-Rocci). It has a high systolic value (normal 120 mmHg) and low diastolic value (normal 80 mmHg). The difference between two is called pulse pressure.

Hypertension (hyperpiesis)

It is sustained the rise in arterial blood pressure or high blood pressure with systolic more than 140 mmHg and diastolic more than 90 mmHg. The reason is stiffening of arterial walls due to cholesterol walls, varicose veins, obesity, toxins, hormones, defective kidney etc. Other forms of hypertension are known as primary hypertension. It accounts for 90% of the cases.

High blood pressure harms three vital organs-heart, brain and kidney. It makes the heart to overwork due to which congestive heart disease develops quite early. A blood pressure of 220/120 mmHg may cause internal hemorrhage due to rupturing of some blood vessel. Cerebral hemorrhage causes stroke or CVA. Damage to optic arteries leads to blindness while a similar damage to renal vessels causes nephritis. It leads to renal failure.

Hypotension (hypopiesis)
It is low blood pressure with systolic below 110 mmHg and diastolic below 70 mmHg
Hypertension is caused by low metabolic rate, starvation, anemia, chronic vasodilation of arterioles, lower pumping activity, valvular defects, nervous disorders, Addison’s disease.
There is an increasing relationship between the rate of heart beat and blood pressure. The phenomenon is called Marley’s law of heart

16.0 **Double circulation**

Double circulation is the passage of same blood twice in the heart through separate pathways for completing one cycle. It causes only 25% of the blood being oxygenated at one time.
Double circulation consists of two parts, pulmonary circulation, and systematic circulation.

1) **Pulmonary circulation:** The movement of blood between heart and lung is called pulmonary circulation.
Deoxygenated blood from the body enters right atrium. It is passed to the rightventricle and then into a pulmonaryarch sending to lungs for oxygenation. From lungs, the oxygenated blood is brought into left atrium
Systematic circulation: This is a movement of blood between the heart and different parts of the body except for lungs. Oxygenated blood is received by left atrium. It is passed to left ventricle which pumps it into the aorta for supply to body parts including walls of the heart. On deoxygenation, the blood passes back into the right atrium of the heart through the coronary sinus, inferior vena cava, and superior vena cava. The purpose of systematic circulation is to transport $O_2$ and nutrients to tissue and remove $CO_2$ and nitrogenous waste from them.

Arterial system

- It comprises all the arteries coming out of the heart and supplying blood to different parts of the body. The heart gives out two main arterial vessels, pulmonary arch (from right ventricle) and aorta.
- Pulmonary arch carries deoxygenated blood. It divides into two pulmonary arteries one for each lung. Aorta carries oxygenated blood. It is swollen into the aortic sinus at its origin. Aortic sinus gives out right and left coronary arteries to the heart. Aorta then produces a short and wide innominate on right side, a left common carotid and a left subclavian before bending down as the dorsa aorta. Innominate or brachiocephalic forms a right common carotid and a right subclavian. Subclavian provides oxygenated blood to forelimbs, chest and spinal cord. Carotids supply oxygenated blood to neck, face, mouth, eyes, scalp, and brain.
• Dorsal aorta has two parts, thoracic and abdominal. Thoracic aorta gives out esophageal (to the esophagus), phrenic (to the diaphragm), branches to back and intercostals (to intercostal muscles) in the thoracic cavity. Abdominal aorta supplies blood to visceral organs and lower extremities. It first gives out thick celiac artery with branches like hepatic (liver), gastric (stomach), splenic (spleen), duodenal (duodenum) and pancreatic (pancreas). Below celiac, abdominal aorta gives out a superior mesenteric artery (small intestine), two super renal (adrenal or suprarenal glands), two renal (kidneys), two genitals and inferior (posterior) mesenteric artery (large intestine) and then divides into two iliac (pelvic region and lower limbs)

• 4% of arterial blood passes into the heart, 10% to the liver, 8% to the brain, 15% of the digestive tract and the remaining for rest of the body.

18.0 **Venous system**

• It comprises all the veins that bring blood to the heart. The venous system consists of pulmonary veins, coronary sinus, portal system and venae cavae. Pulmonary veins are four in number, two from each lung. They bring oxygenated blood to the left atrium. Coronary sinus collects deoxygenated blood from all the walls of the heart. It opens into the right atrium. Superior vena cava is formed by two brachiocephalic veins each of which receives deoxygenated blood from a jugular vein (from head and neck), subclavian vein (upper limb) and internal thoracic vein (part of the chest). Before opening into
the right atrium, superior vena cava receives a small azygos vein from the esophagus and intercostal area.

- Inferior vena cava is formed by the union of two common iliac veins (pelvis and lower limbs). While on its way to the heart, it receives genital veins (gonads), lumbar veins (muscles of the back), renal (liver) and phrenic veins (diaphragm). It then opens into the right atrium.

19.0 Portal system

- It is a system made of a portal vein and the capillary complex formed by it in an organ than one of its origins. A portal vein is a vein which collects blood from one organ by a set of capillaries and distributes that blood into a second organ through another set of capillaries instead of sending blood into the heart. There are three types of portal systems – hepatic, hypophysial and renal.

19.01 Hepatic portal system

- It occurs in all vertebrates and is meant for taking blood from digestive tract, pancreas, and spleen into the liver. The system has a large hepatic portal vein that is formed by four veins- splenic (spleen), inferior mesenteric (rectum and the distal part of the colon), superior mesenteric (small intestine, caecum and proximal part of the colon) and gastroepiploic (from stomach and pancreas). Hepatic portal vein enters liver and breaks into capillaries. The system function as a short circuit for (i) Removal of glucose, amino acids, and other nutrients. (ii) Deamination of extra amino acids and conversion of harmful ammonia into urea (iii) Separation of toxic chemicals and their detoxification.
Direct pouring of liver products into venous blood

19.02 Hypophyseal portal system

It is a minor portal system that occurs in higher vertebrates. The system consists of a single hypophysial portal vein. The portal vein is formed by capillaries in the hypothalamus. It passes into the anterior lobe of pituitary glands and breaks up into capillaries there. The hypophyseal portal system is meant for pouring hormones secreted by hypothalamus directly into the anterior part of the pituitary.

19.03 Renal portal system

It occurs in lower vertebrates (fish and amphibians), reduced in reptiles and aves and is absent in mammals. It consists of renal portal veins that bring blood from a posterior part of the body directly into kidneys for removal of waste products.

20.0 Lymphatic system

It comprises lymph, lymphatic capillaries, lymphatic vessels, lymphatic nodes and lymphatic ducts.

20.01 Lymph

Lymph, a colourless fluid is a part of tissue fluid, which in turn, is a part of blood plasma. So the composition of tissue fluid and lymph is same as that of blood plasma but it lacks RBCs and large plasma proteins. As compared to the tissue fluid, the lymph contains very small amount of nutrients and oxygen but contains abundant
Lymphatic capillaries lie close to the blood capillaries but differ from them to extent that they end blindly. Moreover, they have extremely thin walls. They are composed of a single layer of endothelial cells. The lymphatic capillaries of intestine absorb the digested fats. They are milky in appearance and are, therefore, called the lacteals.

20.03 Lymphatic vessel

The lymphatic capillaries unite to form large lymphatic vessels. They are composed of an outer coat of fibrous tissue, middle coat of muscular tissue and an inner lining of endothelial cells. The lymphatic vessels have numerous valves.

20.04 Lymph node

- These are small oval or bean-shaped structures located along the length of lymphatic vessels. Lymph nodes are most
Both B-lymphocytes and T-lymphocytes are produced here.

- Macrophages of lymph nodes remove bacteria, foreign material and cell debris from the lymph.
- B-lymphocytes change to plasma cells that produce antibodies against invading antigens, while T-lymphocytes attack cells that are ‘foreign’ to the host body.

20.05 Thoracic duct

The lymphatic vessels of left side unite to form a thoracic duct. This duct begins at the cisterna chyli, which is a sac-dilation situated in the front of the first and second number vertebrate. The thoracic duct contains several valves. It discharges its lymph into the left subclavian vein.

20.06 Right lymphatic duct

The lymphatic vessel of the right side of the thorax, head, and neck unite to form the right lymphatic duct. It is about 1 cm in length. It discharges its lymph into the right subclavian vein.

20.07 Lymph movement

The lymph flows in lymphatic vessels very slowly. Forcing out of fluid from the blood capillaries sets up some pressure in the tissue fluid. This establishes a pressure gradient in the lymphatic, causing the flow of lymph in the latter. Movements of viscera and contractions of the body muscles help considerably in squeezing the lymph along. The valves present in lymphatic vessels prevent its backflow. Movement of villi assists flow of lymph in the lacteals. Gravity helps in moving the lymph down the lymphatic vessels of head and neck.
20.08 Functions of lymph

The lymph or lymphatic system serves functions as:

- It drains excess tissue fluid from the extracellular spaces bin to the fluid.
- Some of the fluid from the digestive tract is absorbed into the lymph. The lymphatic vessels store this fluid temporarily and release it gradually so that the kidney does not face a sudden pressure of urine excretion.
- It carries carbon dioxide and nitrogenous waste materials that diffuse into the tissue fluid to the blood.
- It takes lymphocytes and antibodies from lymphatic nodes to the blood.
- It transported fat that is digested and absorbed in the intestine to the blood in the form of chylomicron droplets.
- It destroys the invading microorganisms and foreign particles in the lymphatic nodes.
It brings plasma protein macromolecules synthesized in the liver cells and hormones produced in the endocrine glands to the blood.

20.09 Spleen

The spleen is the largest component of the lymphatic system. It is large (7-10 cm in diameter), bean-shaped, vascular, dark red organ located in the abdomen just below the diaphragm at the tail of the pancreas behind the stomach.

The spleen is composed of red pulp (reticular tissue rich in RBCs) having small patches of white pulp (lymphatic nodes) scattered in it. The red pulp is enclosed by a capsule of white fibrous tissue. The capsule sends trabeculae into the pulp and is surrounded by visceral peritoneum.

20.09.01 Functions

i) Destruction of worn-out red corpuscles
ii) Reservoir of red corpuscles
iii) Formation of agranulocyte
iv) Production of antibodies
v) Storage of iron
vi) Erythropoiesis
vii) Disposal of foreign elements

20.10 Thymus

The thymus is also a lymphatic organ. It lies in the upper chest near the neck. It is prominent in children but begins to degenerate in early childhood. It educates the lymphocytes in the foetus to distinguish cells from foreign cells.
2. **Atherosclerosis:**

It is wall thickening and narrowing of the lumen of medium and large arteries. In atherosclerosis, yellowish plaques (atheromas) of cholesterol and other lipids are deposited within tunica intima and inner part of tunica media were smooth muscles abound. They are mostly caused by low-density lipoproteins or LDL which can pass through the endothelium. Plaques grow. The smooth muscles also proliferate probably caused by the release of platelet-derived growth factor (PDGF). This occurs due to the roughness of inner arterial lining. Thickening of arterial
wall reduces the lumen size. In extreme cases, the growth of plaques may completely block an artery. Atherosclerosis leads to hypertension, reduced blood supply to limbs and other organs resulting in their dysfunctioning.

Atherosclerosis in coronary arteries results in reduced O$_2$ supply to heart walls causing angina, myocardial infection or heart attack or stroke.

3. Coronary artery disease (CAD)
Coronary arteries undergo atherosclerosis. There is deposition of calcium, fat and fibrous tissue which results in narrowing of the arterial lumen. The flow of blood in the affected arteries is reduced. The cardiac muscles supplied by the affected arteries will begin to deteriorate. There are thoracic pain, nausea, perspiration and E.C.G changes. The defect can be treated through angioplasty (breaking of arterial blockage by balloon catheter) and bypass surgery.

4. Angina or Angina pectoris
It is recurrent, spasmodic suffocating thoracic (or heart) pain which often radiates to the left arm. Angina is generally caused by the deficient blood supply to heart muscles. It is precipitated by excitement or strenuous physical activity. Angina pectoris can occur in all types of individuals, both men and women of any age. However, it is more common in middle-aged and elderly persons. Reduced blood supply to myocardial muscles occurs either due to constriction or obstruction of blood vessels.

5. Heart Failure
It is the inability of the heart to supply blood in adequate quantities to all parts of the body. Heart failure is a
fragments, air, calcium etc. coming from a larger blood vessel is forced into a smaller or narrow blood vessel resulting in its blockage and hence obstruction of blood circulation.

11. Myocardial Infarction: Complication due to reduced blood supply to heart wall-pain, pallor, perspiration, nausea, ECG changes.

12. Heart Burn (Pyrosis). The sensation of burning occurring in waves in esophagus tending to rise upward towards neck often with reflux into the mouth. It has nothing to do with the heart.
14. Hematoma: Localized collection of usually clotted blood in a tissue or organ due to injury and rupturing of the blood vessel.

<tr>
<th>SA node</th>
<th>AV node</th>
</tr>
</thead>
<tbody>
<tr>
<td>1 SA node stands for sinoatrial node.</td>
<td>AV node stands for the atrioventricular node.</td>
</tr>
</tbody>
</table>
SA node is known as the pacemaker of the heart. AV node is also known as pace setter of the heart.

SA node is the first component of conducting a system of the heart. AV node is the second component of conducting a system of the heart.

SA node is controlled by the autonomic nervous system (ANS). It is innervated by the parasympathetic nervous system by the Vagus nerve. AV node is controlled or influenced by the impulses from SA node.

SA node is located in the superior lateral wall of the opening of superior vena cava (SVC). AV node is located in the posterior septal wall of right atrium just near to opening of the coronary sinus.

SA node has the rate of impulse discharge of almost 90-100 beats per minute. AV node normal firing rate is 40-50 times per minute.

22.0.05 Systole Vs Diastole

1. Systole is the contraction phase of the cardiac cycle of the heart. Diastole is the relaxation phase of the cardiac cycle of the heart.

2. In systole stage, when the heart contracts, it pumps blood from the heart chambers into the aorta and a pulmonary artery. In Diastole stage, when the heart relaxes, it allows the heart chambers to be filled with blood from venacava and pulmonary veins.

3. The blood pressure of the systole stage is high in arteries. The blood pressure of the diastolic stage is low in arteries.
The systolic pressure for a normal person is 90-120mmHg (adult), 95mmHg (infant).

The diastolic pressure for a normal person is 60-80mmHg (adult), 65mmHg (infant).

The systolic pressure undergoes considerable fluctuations at different conditions like the extent of work done by heart.

The diastolic pressure undergoes much less fluctuation in health and remains within a limited range. The increase in diastolic pressure indicates that the heart is approaching towards failure.
